ABSTRACT
Optimal detection of liquid ionization calorimeter signal in experimental particle physics is considered. A few linear and nonlinear approaches for amplitude and arrival time estimation based on the $\chi^2$ function are compared in simulation considering the noise sample correlation introduced by the analog pulse shaper. The estimation bias of the first-order approximation, a.k.a linear optimal filtering, is studied and contrasted to those of the second-order as well as the exhaustive search. A gradient-descent technique is presented as an alternative to the exhaustive search with significantly reduced search time and computation complexity. Results from various pulse shapers including the CR-RC$^2$, CR-RC$^3$, and CR$^2$-RC$^2$ are also compared.

Keywords: Liquid Ionization Calorimeter; Detection; Optimal Filtering; Amplitude and Timing Estimation; $\chi^2$ Function; CR$^m$-RC$^n$ pulse Shaper; Linear Optimal Filtering; Exhaustive Search; Gradient Descent; Monte Carlo

1. Introduction
In particle physics experiment, it is common to measure the small charge signal collected by the detector in presence of electronic noise. A collection of data acquisition and signal processing techniques are well developed to optimize the signal-to-noise ratio (SNR) in such systems [1]. Due to the recent development of optical transmission techniques, a trend in detector readout system design is to continuously digitize the detector signal and continuously transmit the data out of the front-end to the control room, in which complex signal processing can be imposed to improve the overall detector system performance [2]. This paper reviews several of such signal processing techniques for liquid ionization calorimeters and compares their performance in simulation. A novel accurate, fast, and low-cost gradient-descent technique is also introduced in the paper.

2. Liquid Ionization Calorimeter
Liquid ionization calorimeter is an energy-measurement detector widely deployed in many particle physics experiments [3-6]. Since the liquid gap between the electrode plates is narrow, e.g., about 2 mm in ATLAS liquid argon calorimeter, the ionization triggered by the electromagnetic shower is instantaneous and the process is followed by a drift of the electrons towards the anode plate. Thus, the detector output signal is modeled as a triangular current pulse. Liquid ionization calorimeter usually exhibit so long drift time, dependent on the drift velocity and the gap size [7]. For example, the drift time in ATLAS liquid argon calorimeter is about 450 ns, much longer than the bunch crossing time which is 25 ns. To avoid long dead time and to reduce noise in the measurement, a CR$^m$-RC$^n$ pulse shaper – a chain of integrator (RC) and differentiator (CR) circuits – is always employed in the analog front-end before digitalization [8]. The general transfer function of a CR$^m$-RC$^n$ shaper is given as follows.

$$H(s) = \frac{(sr_s)^m}{(1 + sr_s)^{m+n}} \quad (1)$$

where $r_s$ is the time constant of the shaper. An intuitive way of understanding the functionality of the shaper is that the integrator limits the input bandwidth and slows down the rising edge of the current pulse for analog-to-digital conversion (ADC) while the differentiator restores the baseline quickly by removing the long tail of the pulse to reduce the possibility of signal pileup. Carefully choosing the time constant $r_s$ gives a smooth shaper.
output waveform with minimal pedestal recovering time, which can largely relax the ADC sample rate while retaining sufficient samples for post-processing.

Figure 1 sketches the shaped waveform as well as the triangular current pulse from the detector. The parameters used for modeling waveforms in Figure 1 are extracted from [9] for ATLAS liquid argon calorimeter, e.g., a CR-RC\(^2\) shaper with \(\tau_s\) set to 13 ns, and the output peaking time is approximately 50 ns.

3. Detection and Signal Processing

While detection is a general signal-processing topic that has been well studied, what we are most interested in particle physics experiments is how to precisely measure the amplitude and timing information of the sampled waveform of the detector output – the amplitude \(A\) represents the energy of the incident particle shower and the timing signifies the arrival time \(\tau\) of the particle thus our ability to correlate signals and events in time.

The general approach of determining amplitude and timing information from limited number of samples can be derived from the theory of optimal filtering \([1,10]\). The technique in the core constitutes a search algorithm to project the samples to the known signal space of the detector front-end including the preamplifier, the shaper, and the analog-to-digital converter to maximize the SNR. Two leading noises are typically e.g., thermal noise and shot noise, are white. Temporal correlation however is introduced by the detector front-end processing, particularly the pulse shaper, and needs to be considered in the optimization procedure. Unlike the stochastic deteriorating effect of electronic noise, the signal pileup by nature is deterministic and should be treated as inter-event interference (IEI). In particle detectors operating at high luminosity levels, many events are produced at each bunch crossing. The densely packed calorimeter cells and the long tail of the detector current pulse tend to aggravate the IEI problem, leading to an equivalent model termed pileup noise to highlight the statistical property of the effect rather than its deterministic physical origin.

Many works have been reported for detector signal processing and some are cited as follows. A linear optimal filtering approach was reported in \([10]\), in which the amplitude and arrival time of the incoming pulse are estimated by the weighted sum of a few relevant samples of the ADC output. The noise autocorrelation matrix is utilized in this technique to improve the estimation accuracy. With the continuous data output in the upgraded ATLAS liquid argon calorimeter, a Wiener filter approach was reported to reduce the pileup noise \([11]\).

4. Monte Carlo System Model

A Monte Carlo simulation platform for modeling the analog front-end of liquid ionization calorimeter is constructed in MATLAB\textsuperscript{®} / SIMULINK\textsuperscript{®}. The model takes into account the detector noise and the input-referred front-end electronic noise as well as the shaper frequency response. Other design parameters are extracted from ATLAS calorimeter system \([9]\) – the ionization current for EMB (electromagnetic barrel) is approximately 3\(\mu\)A/GeV, the typical value for charge drift time is 450 ns, a bipolar CR-RC\(^2\) shaper with a time constant \(\tau_s\) of 13 ns, and a sample rate of 40 MS/s which yields five signal samples to be used for estimation. The peaking time at the output of the shaper is close to 50 ns due to the contribution from the shaper and the RC delay of the preamplifier. The CR-RC\(^2\) shaper is a good compromise between the number of filtering stages, power dissipation, and performance. In our model, the ADC quantization noise is not included.

In the simulation, the front-end electronic noise is assumed to be Gaussian distributed with a standard deviation of 10% of the peak value of the current pulse. Detector calibration is assumed and the ideal output pulse shape is known a priori.

5. Amplitude and Timing Estimation

In line with the differing physical origins of the electronic noise, pileup noise and their effects on the detection process, we will concentrate on the amplitude and timing estimation for liquid ionization calorimeters considering electronic noise only in the rest of this paper. Pileup noise will be reported in a future study.
5.1. $\chi^2$ Exhaustive Search

Considering the correlation between the noise samples introduced by the shaper, the $\chi^2$ function can be defined as follows [10]:

$$\chi^2 (A, \tau) = \sum_{ij} \left( S_i - AG(t_i - \tau) \right) V_{ij} \left( S_j - AG(t_j - \tau) \right)$$  \hspace{1cm} (2)$$

where $V_{ij}$ is the weight matrix for the measured samples. $V$ is the inverse of the noise autocorrelation matrix $R$ with $R_{ij} = <n_i \cdot n_j>$ and $n_i$ is the noise sample.

The $\chi^2$ function defines a non-negative quadratic error surface as a function of $A$ and $\tau$ between the noisy samples $S_i$ and the known pulse shape $g(t_i)$ as sketched in Figure 2. A straightforward approach to determine the best estimate for $A$ and $\tau$ is to perform an exhaustive search on the error surface. Albeit not computationally efficient, the exhaustive search result establishes a baseline for the estimation approaches covered in the subsequent sections.

The Monte Carlo simulation results of the $\chi^2$ exhaustive search are shown in Figure 3 and Figure 4. The performance of the method is limited by the finite step size employed by the search algorithm. No obvious trend for the estimation error is observed.

5.2. Least-Square Exhaustive Search

The derivation of the weight matrix $V$ (or the noise autocorrelation matrix $R$) requires precise knowledge of the impulse response of the detector front-end. The computation of the $\chi^2$ function in Eq. (2) also dictates $N^2$ multiplications for $N$ samples when the off-diagonal entries of $V$ are nonzero. In practice, the magnitude of the off-diagonal entries of $R$ can be small relative to the main diagonal entries. In such cases, the $V$ matrix can be well approximated by the identity matrix. Thus, Eq. (2) reduces to

$$\chi^2 (A, \tau) = \sum_i \left( S_i - AG(t_i - \tau) \right)^2$$  \hspace{1cm} (3)$$

This is identical to the least-square metrics to fit $N$ samples to the known pulse shape $g(t)$.

In our Monte Carlo simulation, the above argument is confirmed with a CR-RC pulse shaper. Again, an exhaustive search is employed to determine the optimal fit of the five samples to $g(t)$. The estimation errors for $A$ and $\tau$ are plotted in Figure 4 and overlaid with the $\chi^2$ exhaustive search results – the two results are nearly identical.

Figure 3. Histogram of 100 Monte Carlo runs for amplitude (left) and arrival time (right) estimation using the $\chi^2$ exhaustive search method. The standard deviation of the detector noise is set to 10% the peak value of the detector current pulse. The sample period $T = 25$ ns, $A_0 = 4.1134 \times 10^{-7}$, and $\tau_0 = 3$ ns.

Figure 4. The $\chi^2$ versus the least-square search results of 1000 Monte Carlo runs: the mean estimation error and standard deviation for amplitude $A_{est}$ (left) and arrival time $\tau_{est}$ (right). $\tau_0 = [-T/2, T/2]$. Other simulation parameters are identical to those of Figure 3.
5.3. $\chi^2$ with First-Order Taylor Expansion

Taylor expansion can be performed on $g(t)$ in the vicinity of $\tau = 0$ to reduce the computation complexity of the $\chi^2$ function, i.e.,

$$Ag(t_\text{est} - \tau) \approx Ag(t_\text{est}) - A\tau g'(t_\text{est})$$

(4)

Where $g'(t)$ is the first-order derivative of $g(t)$. Thus,

$$\chi^2 = \sum_{i,j} (S_i - \alpha_i g_i + \alpha_j g_j') V_{ij} (S_j - \alpha_i g_j + \alpha_j g_j')$$

(5)

where $\alpha_1 = A$ and $\alpha_2 = A\tau$.

Compared to Eq. (2), Eq. (5) defines a first-order approximated quadratic error surface in terms of $A$ and $\tau$. Thus, which can be used to perform a search or to directly derive a closed-form analytical solution to the problem. The latter has been done in [10] and results are quoted as follows

$$\alpha_1 = \frac{1}{\Delta} (Q_2 Q_3 - Q_1 Q_4)$$

$$\alpha_2 = \frac{1}{\Delta} (Q_1 Q_3 - Q_2 Q_4)$$

(6)

where

$$Q_1 = \sum_j g_j V_j g_j$$

$$Q_2 = \sum_j g'_j V_j g_j$$

$$Q_3 = \sum_j g_j V_j g'_j$$

$$Q_4 = \sum_j g'_j V_j g'_j$$

$$Q_5 = \sum_j g_j V_j S_j$$

$$Q_6 = \sum_j g'_j V_j S_j$$

$$\Delta = Q_1 Q_3 - Q_2 Q_4$$

(7)

5.4. Linear Optimal Filtering

A linear optimal filtering technique was proposed in [10] to minimize the computing effort involved in determination of the amplitude and arrival time information. The formulation of the optimal filter is quoted as follows

$$A = \langle u \rangle = \langle \sum_i a_i S_i \rangle$$

$$A\tau = \langle v \rangle = \langle \sum_i b_i S_i \rangle$$

(8)

The coefficients of $a_i$ and $b_i$ are given as

$$a = \lambda V g + \kappa V g'$$

$$b = \mu V g + \rho V g'$$

(9)

where $\lambda = Q_3/\Delta$, $\kappa = -Q_1/\Delta$, $\mu = Q_2/\Delta$, $\rho = -Q_1/\Delta$, and $Q$ and $\Delta$ are defined in Equation (7).

The advantage of this technique is that the filter tap values are pre-calculated. Thus, the computation can be performed on the fly when data samples arrive, suitable for continuously operated detectors such as the proposed upgrade for ATLAS. It is also useful in resource-constrained implementation, e.g., FPGA or DSP, or latency-sensitive applications.

It can be shown that linear optimal filtering is equivalent to the $\chi^2$ method of first-order approximation [10]. The simulation results of both for $A$ and $\tau$ are illustrated in Figure 5. It is interesting to note that the estimation error exhibits a quadratic dependence on $\tau$ as predicted by Eqs. (4) and (5) truncating the second- and higher-order terms in the Taylor expansion.

5.5. $\chi^2$ with Second-Order Taylor Expansion

The first-order Taylor expansion of the $\chi^2$ function leads to a rather large estimation error or bias when $\tau$ is large $>4.9\%$ for amplitude and $12\%$ for arrival time when $\tau$ reaches $\pm$7/2 in Figure 5. One way to mitigate the large error is to iterate the series expansion and Equation (5) by re-calculating the $g'$ and $Q$ or, in the linear optimal filtering case, re-derive the filter tap values $a_i$ and $b_i$ and iterate Equation (8). Simulation results are shown in Figure 6 for linear optimal filtering with two iterations. The computing overhead in either case is significant. Another solution is to resort to a second-order Taylor expansion,

$$Ag(t_\text{est} - \tau) = Ag(t_\text{est}) - A\tau g'(t_\text{est}) + \frac{1}{2} A\tau^2 g''(t_\text{est})$$

(10)

Where $g''(t)$ is the second-order derivative of $g(t)$.

Figure 5. The simulation results of 100 Monte Carlo runs for the first-order $\chi^2$ exhaustive search, linear optimal filtering, and second-order $\chi^2$ exhaustive search: the mean estimation error and standard deviation for amplitude $A_{\text{est}}$ (left) and arrival time $\tau_{\text{est}}$ (right). Simulation parameters are identical to those of Figure 4.

5.6. Gradient Descent Approach

As simulation results evidenced so far, the exhaustive search approach produces the best estimation accuracy at the cost of high computation complexity. To improve the efficiency of the search, a gradient-descent approach is devised. As illustrated in Figure 2, the bowl-shaped error surface of the $\chi^2$ function exhibits a global minimum. Starting from a random initial point on the surface, a search direction can be derived by comparing the value of the function at the current position to those offset by a step size away in both $A$ and $\tau$ direction. The current position is then advanced in the direction that minimizes the function value. The process is iterated until convergence at the bottom of the surface. Simulations for the gradient-descent approach were performed with four random starting points and the resulting search paths are plotted in Figure 7. Comparing to the exhaustive search method in which the whole error surface is evaluated, the gradient-descent approach significantly reduces the computation involved. Table 1 compares the typical required number of iterations for the two cases.

6. Other Shapers

The amplitude and timing estimation techniques covered in Sec. 4 are also tested with CR-RC$^3$ and CR$^2$-RC$^2$ pulse shapers. For the same 40-MHz sample rate, the peak of $g(t)$ falls in the middle between two samples in contrast to the case of the CR-RC$^2$ shaper in which the peak is very close to a sample point. Figure 8 and Figure 9 plot...
the simulation results for the amplitude and timing estimation along with the input and output waveforms of the shaper. The skewed error curve reveals the asymmetry of the series expansion at off-peak sample points.

7. Conclusions

Monte Carlo simulation results of various amplitude and timing estimation techniques for liquid ionization calorimeter signal processing are presented and compared. The tradeoff between computation complexity and estimation accuracy is studied. With the projected computing power and cost scaling for digital electronics in the future, the gradient-descent technique introduced in this paper can potentially become the leading approach for future nuclear/particle physics signal processing.
